

AI-Quantum convergence in Health Tech

ICC26119

Rema V, Assistant Professor, Department of Data Sciences & Analytics, Head – Centre of AI for Social Good, School of Social Sciences, Ramaiah University of Applied Sciences, Bengaluru, remav.ss@msruas.ac.in prepared this case solely as a basis for classroom discussion. This case is not intended to serve as an endorsement, source of primary data, or illustration of either effective or ineffective managerial decision-making. Certain names and other identifying details have been disguised to protect confidentiality

Case Abstract

The increasing convergence of quantum computing and artificial intelligence (AI) in health technology innovation is examined in this case study. The study explores how quantum computing is being positioned as a supplementary capability to AI in addressing intricate, data-intensive healthcare concerns, drawing on secondary sources. Quantum computing has potential benefits in optimization, molecular simulation, and high-dimensional data processing, yet AI still dominates clinical decision support, imaging, and predictive analytics. The case examines how AI–quantum integration may improve the speed, accuracy, and scalability of health technology solutions through institutional and industry-led efforts. To assess technology preparedness, ecosystem collaboration, and governance considerations, the study takes an innovation and systems viewpoint. The focus of the case is discussion on a suitable balance between prospective clinical benefits and related hazards in the face of uncertainty around quantum maturity, high prices, and skill gaps. The scope also includes identifying healthcare sub-domains where AI–quantum integration is currently possible, such as drug discovery, precision medicine, health operations, system optimization, medical imaging etc. Analyzing the ethical, legal, and data governance issues that could influence responsible adoption in line with both public interest and innovation goals shall remain a critical concern to address.

Background

Over the past few decades, *technology* has been at the forefront when discussing the future of any domain, whether be it retail, banking, manufacturing, hospitality, etc., with healthcare being no exception. Information technology has been transforming the globe at an astounding rate. *Digital Health* has become a buzzword today which signified the nexus of latest technologies in healthcare to support data-driven decision making for the patients' well-being. The first documented use of telemedicine, the use of electronic communication for medical purpose dates to 1897. Digital health saw its development phase from 1950 to 1999, where advances like DNA sequencing, artificial organs, and ultrasound imaging extended digital health beyond telemedicine to encompass roles in diagnosis and treatment. The development of digital communication in healthcare was accelerated by the emergence of professional associations in the 1980s and 1990s such as the International Medical Informatics Association, the American Telemedicine Association, and the European Health Telematics Association (EHTEL). The early 2000s saw a shift towards digitization, aided by growing internet adoption and with the emergence of new subfields such as mHealth (mobile health), eHealth

(electronic health), and personalized health. Companies in Digital therapeutics that used digital technologies to treat medical disorders became popular around 2005. The invention of Fitbit in 2007 signaled the rise of consumer health wearables, bring digital health to every household. In 2017, the US Food and Drug Administration (FDA) established the Digital Health Unit to promote digital health technology, which marked a significant milestone. Investments in digital health increased by more than two-fold, \$4.1B in 2014 to \$9.4B in 2020, making it central to healthcare innovation. The COVID-19 pandemic in 2019 paved the way for the rise of adoption of digital health systems globally.

Early advances in *Artificial Intelligence* (AI) focused on enabling machines to mimic human decision-making and actions, with milestones such as the first robotic arm in 1955, ELIZA in 1964 - an early chatbot simulating therapeutic dialogue, and Shakey, the first robot capable of interpreting and executing human instructions, demonstrating AI's practical feasibility beyond theory. AI's medical applications gained traction in the 1970s with systems such as INTERNIST-1, which supported clinical diagnosis and signaled a shift towards AI as a decision-support tool in healthcare. This was followed by influential systems such as MYCIN for antibiotic selection and DXplain for diagnostic assistance and medical knowledge access. The modern era of AI began in the early 2000s with advances in computing power and data processing, as demonstrated by IBM's Watson, whose natural language and reasoning capabilities expanded AI's role from symptom-based diagnosis to complex biomedical discovery and patient-facing support tools, indicating AI's growing integration across the healthcare continuum. Today, AI is used in advancing personalization in medicine, drug discovery, virtual assistance, diagnostics, scheduling, predictive analytics in streamlining operations and many more. Among the critical challenges with responsible AI-integration in healthcare lies in data governance and ethical considerations including privacy related to patient information, handling of data bias and ensuring the human-in-the-loop. Traditional computing methods are frequently limited by their linear scaling and processing capabilities, making it difficult to handle and evaluate healthcare datasets that are developing at an exponential rate. *Quantum computing*, conceptually that emerged in 1980s, lauded for its ability to analyze big datasets significantly more efficiently than classical computers, could be a pivotal answer to these difficulties. While still in the early stages with its penetration in the healthcare sector, as early as 2021, the real-world implementations of quantum computing in healthcare are emerging. The future will be the AI-Quantum synergy manifesting unparalleled precisions, efficiency, and high-level system value, integrated with path-breaking research and innovation in healthcare. Quantum maturity, high prices, infrastructure requirements, ethical, legal, and data governance issues will remain critical areas to be addressed.

AI in Healthcare

Healthcare has been one of the most data-rich sectors, and as per the World Economic Forum report, the global healthcare industry had generated approximately 2.3 zettabytes of data by 2020. The digital initiatives, growing Electronic Health Records (EHR), advancement in AI technologies in Deep Learning, the need for accelerated drug development in therapeutics and building proactive than reactive health systems have resulted in the growing adoption of AI solutions in healthcare. AI systems are dynamic and autonomous, thereby enabling learning and adapting with the data continuum.

AI applications are in several health sub-domains. Analysis of large volumes of patient data, lifestyle patterns and genomics, detection of patterns through machine learning algorithms have enabled prediction of likelihood of diseases in patients to detect early disease indicators and plan preventive strategies. Supervised learning algorithms play a key role in predictive analytics. Based on learning thousands of medical images, the algorithm detects disease incidence when newer images are shown. Repetitive tasks, maintaining clinical records, claims settlement, etc. are carried out through Robotic

Process Automation (RPA) to help clinicians utilize their time judiciously. Coordination of patient scheduling, patient information dissemination, and such other standard services are carried out using Chatbots powered by AI, bringing down the communication overload for clinicians. Conversational AI applications with sophisticated chatbots are also context-aware through Retrieval Augmented Generation (RAG) techniques, enhancing patient experience as they provide personalized support. AI-powered wearables help generate and monitor data on a real-time basis, using which healthcare professionals will be able to provide remote monitoring including detection of anomalies.

Menlo Ventures' Research points to 22% implementation of domain-specific AI tools by healthcare organizations by 2025, which is still significantly low. A human-centric approach to identifying problems that need solution using AI techniques, piloting, integrating within existing workflows, applying tight feedback loops from stakeholders in improvising will augment AI-adoption. Statistical validity, establishing clinical and economic utility will further be drivers of adoption. Statistical validation is ensured through model performance checks, accuracy, reliability, and calibration. The algorithm must be tested in real-time environment, covering geographical and patient diversity to bring generalizability in results. Post deployment requires continuous monitoring for adverse events and necessary incorporation in the model based on stakeholder feedback. AI is here to stay and grow in the upcoming times. Exhibit 1 outlines the short-medium and long-term areas of potential evolution of AI technologies. Key challenges in AI implementation will be in the data quality and access, technical infrastructure, organizational capacity, explainability, adherence to regulations and following of ethical and responsible practices.

Quantum Computing: An Emerging Capability

While traditional computing is deterministic, and is quantified by 0 and 1 or bits, quantum computing is probabilistic, characterized by *qubits*, with a continuous probability of being between 0 and 1, potentially having the scope to store and process much more information. It adopts a parallel than a sequential approach in computing, accelerating the computational speed. At the core of quantum are qubits that can exist simultaneously in multiple states due to superposition enabling quantum computers to perform many several calculations at once. Computation power has only fast-tracked data processing and analysis to support higher accuracy in real-time decision making. With quantum computing picking up, developers are creating quantum machine learning algorithmic techniques to handle large volumes of data at unprecedented speed. There are several exciting uses for quantum computing in the medical field. By analyzing big datasets quickly, it can help with precision medicine and precise diagnosis, allowing for early disease detection and individualized therapies. By using sophisticated machine learning and simulated atomic models, it improves drug discovery and biochemical research. Furthermore, supply chains may be optimized, expenses can be decreased, fraud detection can be improved, and data security can be strengthened using sophisticated encryption techniques.

Convergence of AI and Quantum Technologies

Quantum is changing the frontiers of the health ecosystem. The complexity of health data, multidisciplinary and multimodal investigation of disease trajectories, scale, and pace of executing research by processing big data at enterprise levels necessitates a quantum-integrated approach to AI models and algorithms. Quoting some significant works integrated with industry such as Cleveland's partnered work with IBM in Therapeutics for drug discovery against diseases like COVID using Bayesian optimization-prioritized simulation; advanced AI models to analyze the impact of anti-inflammatory drugs on seizure recurrence in epilepsy patients; multi-modal analytics tools to optimize human

genome sequencing. The landmark ten-year partnership entered in 2021 by them paved the way for such state-of-the-art research. Exhibit 2 depicts potential areas of capabilities where quantum-integrated approach will overcome classical AI related challenges in several sub-domains of healthcare.

Quantum is particularly gaining high traction in drug discovery acceleration, operational optimization, precision diagnostics, and trusted data infrastructure. While AI is used in drug discovery, it still lacks identifying early disease markers, which can be bridged through quantum-integrated algorithms through its high-level simulation power. Quantum technologies are classified broadly into *quantum computing*, *quantum sensing* and *quantum communication*. Quantum computing uses entanglement and superposition to model complicated biological systems, speed up structure-based drug creation, mimic molecular characteristics, and interactions, and optimize computationally difficult processes, which is not in the realm of AI. Quantum sensors have capabilities to advance neurological mapping, and pharmaceutical manufacturing by enabling ultra-sensitive imaging and diagnostics through the measurement of minute magnetic and bioelectric fields in vivo. Through Quantum Key Distribution (QKD) and Quantum Random Number Generators (QRNGs), *quantum communications* provide protection based on both algorithms and the rules of physics, protecting sensitive health data and clinical infrastructure. While quantum pushes the limits of science and computation, AI fortifies the digital and operational underpinnings of healthcare. Early detection, more accurate treatments, robust data infrastructures, and new research capabilities will all be made possible by their integration.

To drive quantum innovation, the health ecosystem outlines three broad roles – *Creators*, *Deliverers* and *Enablers*. Pharmaceutical labs, pharma companies, genetics research institutes, biotech firms, diagnostics providers, and technology start-ups will play the role of ‘Creators’ as the originators of biomedical breakthroughs. Hospitals, clinics, medical device providers, payer-provider networks, and pharmacy chains will be the ‘Deliverers,’ instrumental in turning innovation into tangible health outcomes, right at the frontline of patient care. The ‘Enablers’ comprising of regulatory authorities, standard setters, global and national health agencies, technology, and infrastructure providers such as the IT networks, security, hyperscalers, High Performance Computing (HPC) centers will be at the helm of setting fast track approvals for digital health tools, standardize frameworks for data interoperability, to shape how new technologies are adopted and scaled.

The maturity levels of quantum applications are very different, with use case applications in the phase of commercial readiness within 2 years, prototype readiness in 3 to 5 years, experimental readiness in 6 to 10 years and theoretical readiness in a timeline requiring more than 10 years. Let us analyze maturity levels for use cases in the Creator-segment of this ecosystem. Quantum technologies in the biomedical space, particularly sensors have seen active Research-Use-Only (RUO) deployments and have demonstrated commercial readiness. Their integration in existing workflows will be the next steps. With prototype readiness and academic validation in place are several use cases in molecular dynamics simulations, mRNA secondary structure prediction which require targeted pilots in collaboration with pharma companies and validation standards set by regulators to make it actionable. Use cases in protein folding prediction and photodynamic property modelling are in the experimental phase, demonstrating technical feasibility but not enterprise-ready yet, which require joint academic and industry research to validate performance on real data. Use cases such as biological simulation of treatment responses are theoretical at present, but would seek investment in exploratory research to research on future capabilities. With respect to the Deliverers-segment, Magnetocardiography (MCG) for cardiac imaging, operating room block scheduling are among applications that have already seen commercial and early clinical use in the US hospitals. Quantum biomarker algorithms, quantum-secure hospital data links are among key examples in the prototype phase which require pilot launches in specific departments to monitor in real patient cohorts. In the experimental phase of readiness are

use cases such as quantum neural networks for surgical risk prediction, early lung cancer detection biomarkers using hybrid quantum classical biomarker modelling which seek development of hybrid workflows and regulatory compatibility for implementation. Building capacity for clinical validation by investing in protocols will support use cases that are in the continuum of quantum-secure healthcare networks that are currently in theoretical phase. Regulatory ambiguity is a roadblock that prevents the availability of cutting-edge technologies to promote better health systems. Maintaining momentum and building trust requires a strong ethical framework that balances innovation and patient safety. This shall be discussed elaborately in the upcoming section.

Co-designed solutions involving research institutions, healthcare organizations, quantum developers, and industry is essential to accelerate quantum-led innovation and mitigate risks related to access, development, and deployment. Quantum-readiness can be possible only with combined efforts of all stakeholders particularly related to validation of quantum computing and sensing tools. Co-investment by governments and industry in secure infrastructure and talent development will build capabilities of adoption. Leadership alignment to support research priorities engrained in quantum-integrated approaches is critical. At the deployment levels, upgrading EHR exchanges, enabling QKD architectures for pharmacy systems, imaging transfers, etc. will enable protection of highly confidential clinical health workflows. By integrating quantum sensing and diagnostic decision support tools, operational efficiency can be achieved through cost reductions. Multiple public and private funded initiatives should be operationalized to unlock the value of quantum technologies through R&D. Further quantum capabilities need to be built with robust hybrid cloud infrastructure, supporting AI and high-powered computing.

Ethical, Governance, and Policy Considerations

Ethical AI is about responsible integration of AI systems in all phases, starting from *design* - data input phase, *development* - model building phase, and *deployment* - implementing the model and measurement of performance. In the healthcare context the goal will be to promote patient well-being, fairness, transparency, and accountability. Ethical AI implementation looks at addressing the following key aspects – *bias and inequality, data privacy, and consent, explainability, human-in-the-loop and regulatory challenges*. An AI based-model was trained largely on data from US cancer patients, when it was deployed in China and a few other regions, it produced inaccurate treatment suggestions. Here localization is important coupled with human intervention. While the baseline characteristics of the disease may be similar, variation will be in location influence, on treatment adopted, genetics that respond to line of treatments, availability of certain drugs etc. A model when not trained with representation for diverse cohorts, leads to poor outcomes as the model has never learnt those features, resulting in inaccurate predictions. Therefore, bias can make treatments less effective for underrepresented populations. There have been several instances of privacy breach seen in healthcare. A global tech company accessed millions of patient records to develop an app without adequate patient consent or transparency and faced legal action. Some fitness tracking apps were found to share user health data with advertisers or third parties without informed consent. AI in healthcare depends on large datasets of sensitive patient information. Without proper consent, de-identification, and storage safeguards, privacy violations can occur. The solution to privacy-management is Federated Learning, where in AI models train on data from multiple hospitals or devices without sharing raw patient data, the learned patterns and model updates are shared ensuring privacy and prevention of data leaks.

Deep learning systems, often act as ‘black boxes’ where there is output, but clearly no know-how of how or why it arrived at that decision. In healthcare, clinicians must be able to justify every medical

decision with clear reasoning. Lack of explainability can cause clinical hesitation, and reduced adoption by doctors. 'Human-in-the-loop' ensures that doctors and not machines make final healthcare decisions. AI should support, not replace clinical judgment. For example, when certain hospitals in the US used fully automated sepsis alert systems, false alarms sometimes overwhelmed clinicians. Systems like Johns Hopkins' Sepsis Watch improved outcomes by ensuring nurses verified alerts before action. Although AI assists with precision in surgical robotics, a human surgeon always controls the final movement and response. Human oversight ensures accountability and patient safety. Regulatory framework in AI, whether globally or in Indian context are clearly fragmented. Implementation tends to rely on sectoral rules such as health data, medical devices etc., rather than a unified AI regulatory regime. AI that learns and adapts post-deployment creates regulatory challenges not fully addressed. Without clear laws, it is uncertain who is liable if AI makes a wrong diagnosis or harms a patient.

In a nutshell, AI and quantum technologies have fragmented regulations creating governance complexities. There is a dire need for governance frameworks for ethical implementation of these technologies. AI-literate, quantum-aware healthcare professionals at leadership levels will be instrumental to enable their implementation. The interoperability gaps due to fragmented digital infrastructure can limit the scale of these technologies. Exhibit 3 details out the timelines of major AI regulations and governance frameworks.

Regulatory foundations need to be established, foundational steps would be adoption of National Institute of Standards and Technology (NIST) - post-quantum cryptographic protocols across health IT baselines and procurement frameworks, launch of hospital-to-hospital QKD pilots to validate secure quantum communication in clinical contexts. Setting up of foundational governance and compliance runbooks to standardize early adoption is the key. Once pilots are proven in a timeframe of initial two years, scalability will be the next step. National alignment on QKD, post-quantum and HPC-integration standards across hospitals and agencies will be critical. Institutionalizing in the next seven to ten years will need development of cross-border data-sharing frameworks integrating quantum security for clinical and research exchange. It will necessitate certification and procurement rules with quantum-secure standards. Governance frameworks enabling international coordination and oversight will be significant in achieving sustainable adoption of quantum technologies. One significant regulation is the Quantum Computing Cybersecurity Preparedness Act, a US federal law passed in December 2022 which required developing a plan for migrating agency IT to post-quantum cryptography (PQC) to ensure organizations will be able to resist cyberattacks from advanced quantum computers. There is a need to formalize guidelines for healthcare organizations globally for transitioning to quantum-safe cryptographic solutions without disrupting the patient care.

Looking Ahead

In 2024, the World Health Organization (WHO) outlined a set of strategic priorities to govern the responsible integration of AI into healthcare systems. These priorities underline the importance of strong expert guidance and governance systems that meet ethical concerns, regulatory constraints, and accountability procedures. They also emphasize the significance of developing defined benchmarks, testing methodologies, and performance criteria to ensure that AI applications in healthcare are safe, dependable, and effective. Recognizing the human dimension of digital transformation, the emphasis is in investment in knowledge sharing and workforce development to create an AI-ready healthcare workforce. In parallel, applications-oriented, and evidence-based research was advocated to determine the real-world effectiveness, practicality, and impact of AI

solutions in healthcare. The importance of localizing and customizing AI models to reflect diverse healthcare contexts and population needs, as well as encouraging community engagement and multi-stakeholder collaboration via platforms that enable shared learning, coordination, and responsible innovation is highlighted as the way-forward.

The CB Insights, a market intelligence and analytics company reported Hospital AI Readiness Index that evaluated hospitals' ability to develop and deploy AI using a 0 -100 composite score that combines indicators of *innovation* such as research, patents, and partnerships; and *execution* including real-world deployment and operational use of AI tools. These signals are pooled using unique benchmarking methods to produce a relative readiness score, which allows for cross-hospital comparison (Exhibit 4). Mayo Clinic's comparatively high level of AI innovation is the main reason it leads in AI readiness with over 50 patent applications submitted in fields including cancer and cardiovascular health. Its investments in AI-powered businesses in use cases of surgical intelligence and clinical documentation have been significant. Intermountain real-time clinical decision support platform developed internally is noteworthy. Cleveland on the other hand has strong business partnerships such as with PathAI, focused on using pathology algorithms to improve clinical care and translational research. Innovations in clinical research coupled with strategic industry collaborations will be the catalysts to strengthen development and deployment of latest technology in real-time.

Exhibit 2: Potential Capability Areas for AI–Quantum Integration in Healthcare

Capability Dimension	Quantum enhanced potential	Healthcare sub-domain
Data volume, speed, and computational efficiency	Accelerated optimization and simulation for large and high-dimensional healthcare datasets such as molecular structures, imaging features, and clinical variables, for problems that are computationally intractable using classical methods alone	Molecular modeling in drug discovery, large-scale epidemiological simulations, advanced population health modeling
Complex pattern recognition and learning	Enhanced optimization of model parameters and exploration of complex feature spaces, improving training efficiency	Early disease diagnosis, risk stratification, personalization in treatment
Cryptography and security	High-level encryption and decryption through QKD	Interoperability of health data, secure exchange of health data and high-level data privacy, privacy-preserving telemedicine systems
Complex optimization problems	Improved solutions for combinatorial and constrained optimization problems that are computationally expensive for classical systems	Hospital resource allocation, scheduling, supply chain optimization
Molecular simulation	Accurate simulation of molecular interactions beyond limits of classical approximations	Drug discovery, precision therapeutics
	Enhanced probabilistic modeling with	Clinical decision support
